MAXIMAL PLANAR GRAPHS & TRIANGULATION

This section investigates the planer graphs with maximal edge desities:

def maximal planar graph: a planar graph that adding any edge would make it non-planar.

eg. (can't add anelye...)

(add on edge would break the inequality |E| <3171-6.)

Maximal planor graphs are interesting because for several reasons. First, they are the "worst & cases" plant but at the same time valuable examples in understanding the properties of planas graphs. Second, due to the "maximality" restriction, they eximinit

very nice structures and could serve as a "normal form" for any planar graphs; we would elucidate this aspect in the following following.

Lemma 14 Every maximal planar graph is biconnected. Proof. Suppose to the Contrary that there's a cut vertex v. It separates G-v into at least two Components A and B.

We inspect the neighbors

A point of v in circular order.

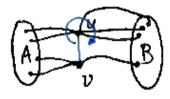

In the beginning, we meet some neighbours from A, and at some point, we see a neighbour from B. Let a∈A be the guy that we saw just before this point, and b∈B be the guy that we see right now.

Since v is a cut vertex, ab & E. However, We could always draw an arc close enough to a v-b to connect a and b So the graph G+ab is still planar, Contradicting maximality.

By a similar agument, we could strengthen Lemma 14:

Lemma 15 Every maximal planar graph is 3-connected.

Proof (Sketch) Suppose to the Contrary that removing u and v would disconnect the graph to A and B.

Note that uve E since the graph is maximal planar and nothing could

prevent us from Commerting un due to our assumption of (< 3)-connectivity.

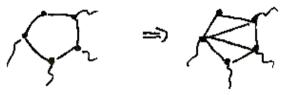

Now we inspect all neighbours of u in Circular order as in Lemma 14, starting from V∈N(u) and running

Replaying the argument in Lemma 14 Would lead us to a Contradiction.

These results over not so surprising because We expect maximal planar graphs to be denser than a tree or a cycle.

Observing the examples we gave (and maybe

other examples you draw yourself), we Spot that a maximal planar graph is full of "triangles". Intuitively it's clear as well: if there's a the face bounded by (≥4 edges, why not add a chord to "triangulate" it?

Applying such intuitive argument needs special care, however. There are at least a pitfalls:

(1) A face bounded by 24 edges doesn't necessarily has a good-looking, Cyclic boundary. Perhaps it looks like

(a) Even if it looks nice, we should ensure that we don't add a chord that already

These pitfalls could be avoided, which we shall do right away.

Lemma 16 in particular, maximal planar graph is face in a bounded by a cycle.

Proof. Suppose there's a face f where of is not a cycle. But of can't be a tree, for otherwise any e \(\int\) of has both sides incident to f and thus e doesn't lie on a cycle in G, contradicting biconnectivity.

25 Harris

So of contains at least a cycle. We walk through of and output the sequence of vertices we encounter in each step.

e.s. = (1,4,5,4,6,4,1,2,3)

If If is not a cycle, then the sequence would have a vertex v appearing twice or more. Let u and w be the predecessor and successor of v respectively.

The first of u v w appearance of u v w

By biconnectivity, $\exists a cycle C : uv$ and vw lie on C. By Fordan Curve Theorem (Theorem 4) C has an interior and an exterior. Say the blue area \subseteq interior of C, then f is Enforced to be entirely in the interior of C. But this would

tell us that v cannot appear twice in the Sequence!

This lemma states something obvious and could be accepted as axiom if you don't want to read the proof. Anyway, it resolve the first pitfall and gurantees that all faces look nice in a maximal planar graph.

Theorem 17

Every maximal planar graph is bounded by a triangle.

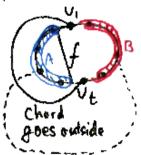

proof. Suppose there's a face f where of is not a triangle. Then by Lemma 16, of is a cycle of length ≥ 4. Denote

Could safely triangulate it by adding chords from the vertex to all non-neighborning vertices. Formally, the edges vivi for all 3≤i≤k-1. Since k≥4 we always add some edge.

This contradicts with maximal planaity.

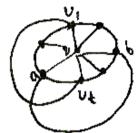

(6) If of contains a chord, say we whog, it would not of into two

parts A and B; both non-empty.

We claim that there's no chords between A and B.
Suppose there's one, then pictorially it must intersect with the chord V. Vt. To

we could add a virtual vertex v at the center of f, and connect ve; (Vi):

[This operation doesn't change planarity]

One would find out that this graph Contains a subdivision of Kr (with vertices pricipal vertices v, u, v, a, b), Contradicting planarity.

So we know no chord could present be A and B. And it's a routine exercise to see we could triangulate f by adding A-B chords, Contradicting the maximal planarity.

Remark. The proof is rather constructive and yields an algorithm to augment any non-maximal planar graph to a maximal planar graph. This is asnally called "topological triangulation" We will look at an efficient implementation (ater.

Corollary 18.

The following state ments are equivalent:

(1) G is maximal planar.

(2) G is planer and Esatisfies | E |= 3 | v | -6.

(3) G is planar and every face is bounded by a triangle (in a chosen embedding).

Proof. Exercise.

We conclude the section by presenting a linear algorithm for triangulating a plane graph. By "plane graph" we emphasised that some geometric aspects of the embedding should be given as input.

Algorithm: Triangulate.

Foreach $f \in F(G)$ do

pick an arbitrary $v \in \partial f$ Let List[v] := list[v] Uff

for each $v \in V(G)$ do | mark all $u \in N(v)$.

foreach $f \in list[v]$ do

go through ∂f clockwise from vif bump into a marked vertex u then

not directly adjacent to

on ∂f

else > >

unmark all $u \in N(v)$

So basically the the "if" corresponds to the case when a chard is related to v, and "else" corresponds to the case where v is chardless.

We did the a preprocessing step that

This is only for efficiency consideration:
To make each face being accessed exactly once in the main loop. It should be clear that the overall running time is linear, since every edge is traversed only 6 times

(2 for marking, 2 for unmarking, and 2 for traversing faces), every vertex is accessed once, and every face is processed once.
